Symbolic Stationarization of Dynamic Equilibrium Models

Fabio Canova[*]   Kenneth Sæterhagen Paulsen [†]

December 20, 2021

Abstract

Dynamic equilibrium models are specified to track time series with unit root-like behavior. Thus, unit roots are typically introduced and the optimality conditions adjusted. This step requires tedious algebra and often leads to algebraic mistakes, especially in models with several unit roots. We propose a symbolic algorithm that simplifies the step of rendering non-stationary models stationary. It is easy to implement and works when trends are stochastic or deterministic, exogenous or endogenous. Three examples illustrate the mechanics and the properties of the approach. A comparison with existing methods is provided.

Keywords: DSGE models, unit roots, endogenous growth, symbolic computation.

1 Introduction

Dynamic Stochastic General Equilibrium (DSGE) models are popular in academic and policy institutions and used for a variety of purposes: informally matching stylized facts present in the data, structural estimation, scenario analyses, and forecasting. Often these models just consider stationary disturbances and a standard production structure with constant returns to scale, making the output a vector of stationary time series. When this is the case, one has to choose how to compare the model to data displaying near non-stationary behavior and how to design estimation and inferential procedures which can cope with the mismatch (see e.g. Canova (2014)).

Alternatively, one could assume that some of the disturbances are non-stationary, for example, assume permanent shocks to total factor productivity. In this case, a balanced growth path must be found prior to the computation of the solution and the optimality conditions transformed so that a stationary equilibrium exits. Standard solution procedures such as Blanchard and Kahn (1980), Klein (2000) or Sims (2010), in fact, work under the assumption that the variables entering the optimality conditions are stationary. Manually performing the stationarization step is cumbersome, it involves tedious algebra and, more importantly, it is prone to mistakes, especially in medium or large scale models featuring a number of non-stationary disturbances.

This paper presents a fast and easy-to-implement algorithm that mechanically performs the stationarization step in models featuring unit roots or deterministic trends, when the sources of the trends are exogenous or endogenous, such as in Comin and Gertler (2006). Because the approach is symbolic, the cost of computations is trivial. Thus a researcher may explore the consequences of alternative assumptions regarding the location of the unit roots (preferences, technologies, policy shocks), examine the equations that are affected, and the implications they have for the observable variables. Such an exercise allows one to improve the specification and the empirical content by confronting the long run implications of the model and of the data systematically.

The output of the algorithm consists of a system of equations containing the stationary version of the original non-stationary model, and it can be written to a text file or exported to LaTeX. The user can thus check that the solution makes sense and then perform a standard dynamic analysis. The algorithm is contained in a package of routines, called NB toolbox (Paulsen (2021)), which also has a number of ready-built functions a researcher can employ for standard dynamic analysis. Given that the stationary model can be written to a text file, the output of the algorithm can also be used as an input in other toolboxes, such as DYNARE, Dynare (2021); IRIS, GPMN (2020); or RISE, Maih (2021), for filtering or estimation, if the user wishes to do so.

IRIS and DYNARE have the capability to deal with non-stationary disturbances in dynamic models. Our approach is more general than both. The first toolbox uses a numerical approach to perform the

stationarization step. Thus, the solution features approximation errors. In addition, the user needs to provide the balanced growth path for the approximation to be performed. The second toolbox needs the user to provide both the growth factors and the variables which are associated with the growth factors. In addition, at the moment, it can handle only exogenous unit root processes.

The rest of the paper is organized as follows. The next section describes the problem to be solved. The algorithm is in Section 3. Section 4 presents the syntax of the model file and the commands. Section 5 has examples. In Section 5.1 we consider a RBC model driven by non-stationary labor augmenting technology shocks. We stationarize the model manually (Section 5.1.1); with our algorithm (Section 5.1.2) and compare the two solutions. In Section 5.2 we repeat the exercise for a larger-scale model with unit root in the labor-augmenting and the investment-specific technologies, as in Justiniano *et al.* (2011)). We compare its long run properties to those of a model where unit roots appear in the production technology and in preferences. Section 5.3 considers a model with endogenous growth and compares manual and automatic solutions. Section 6 discusses the relationship between our approach and existing methods. Section 7 concludes. A number of on-line appendices contain the details and the files mentioned in the text.

2 The problem

The optimality conditions of a DSGE model can be written as:

$$E_t[F(X_{t+1}, X_t, X_{t-1}, A_t, A_{t-1}, U_t, \theta)] = 0, \tag{1}$$

where $F(.)$ is a $M \times 1$ vector of continuous non-linear functions, and X_t is a $M \times 1$ vector of endogenous variables, with the convention that the first R variables are non-stationary, and the remaining M-R are stationary, and U_t is a $N \times 1$ vector of stationary exogenous forcing variables. A_t is a $Q \times 1$ vector of non-stationary forcing variables which, for the sake of the presentation, are assumed to enter without leads, even though this is not a limitation of the approach, as leads can always be considered by extending the vector A_t. A_t may be exogenous or endogenous and, in this latter case, may depend on a subset of U_t, θ and X_t. Finally, θ is a $p \times 1$ vector of structural parameters.

The presence of the A_t in (1) rules out the possibility of using standard perturbation methods to solve the problem, since the Blanchard and Kahn condition fails. However, if the problem has a stationary representation, we can redefine the R endogenous non-stationary variables as $Z_t^i = \frac{X_t^i}{H^i(A_t)}$, $\forall i \in [1, R]$ and the M-R stationary variables as $Z_t^i = X_t^i$, $\forall i \in [R+1, M]$, and proceed in the standard way. Here H^i are continuous differentiable functions of A_t and represents the balanced growth path of the model. Let $\Delta Z_t^i \equiv \frac{H^i(A_t)}{H^i(A_{t-1})} \frac{X_{t-1}^i}{X_t^i}$ $\forall i \in [1, R]$ and $\Delta A_t = \frac{A_t}{A_{t-1}}$ and set $\frac{X_{t-1}}{X_t} = 1$.

Rather than finding the $H^i(A_t)$ functions, which is complicated when R is large, it is easier to compute the functions G^i satisfying $G^i(log(\Delta Z_t), log(\Delta A_t)) = 0, \forall i \in [1, R]$. These functions also characterize the

3

balanced growth path and are obtained with a set of restrictions, stated in Section 3.1. If we let

$$Y_t = \begin{bmatrix} Z_t \\ \Delta Z_t \\ \Delta A_t \end{bmatrix}, \tag{2}$$

a stationary representation of the optimality conditions of the model is

$$E_t[\hat{F}(Y_{t+1}, Y_t, Y_{t-1}, U_t, \theta)] = 0, \tag{3}$$

where $\hat{F}(.)$ is a function representing the non-linear equations, and Y_t has dimension $M + R + Q$. Note that ΔZ_t and ΔA_t belong to a block exogenous system when A_t is exogenous.

In words, our algorithm creates the Y_t from any set of (X_t, A_t, U_t), and transforms (1) into (3). To perform the transformation one needs four steps:

1. Find the restrictions holding in the balanced growth path.

2. Identify the R non-stationary variables.

3. Compute the functions $G^i, \quad \forall i \in [1, R]$.

4. Rewrite (1) into (3).

Clearly, trends must be properly placed for the procedure to succeed, as the restrictions obtained from the first step need not be consistent with balanced growth. For example, it is well know that, with a unit root in government expenditure, there are no restrictions on preferences and technologies producing balanced growth in a standard real business cycle (RBC) model.

3   The algorithm

This section describes the algorithm that automatizes the four steps outlined in Section 2.

3.1   Finding the restrictions holding in the balanced growth

One method to quickly identify which variables are non-stationary is to find the set of restrictions that must hold to rewrite the model in a stationary form. These restrictions are generically given by:

$$K(X_{ss}^{\Delta}, A_{ss}^{\Delta}, \theta) = 0, \tag{4}$$

where $X_t^{\Delta} = log(\frac{X_t}{X_{t-1}})$ and $A_t^{\Delta} = log(\frac{A_t}{A_{t-1}})$, and X_{ss}^{Δ} and A_{ss}^{Δ} are the values along the balanced growth path. Here the function K represents a vector of L linear restrictions. In general, $L \geq M$. Let θ_p and θ_d be two parameters, h and g two generic functions and $h^{\pm}$ a function formed using $h \pm g$. Let c and

v be functions obtained applying the rules described below to h and g, respectively. We can find the restrictions given by K, by applying the following rules to the equations of (1) by forward accumulation, and eliminating all duplicated restrictions [1].

Equal (=)

- If $X_{ss} = Y_{ss}$, then $X_{ss}^\Delta = Y_{ss}^\Delta$.
- If $X_{ss} = h(Y_{ss}, Z_{ss})$, then $X_{ss}^\Delta = c(Y_{ss}^\Delta, Z_{ss}^\Delta)$.
- If $X_{ss} = h^\pm(Y_{ss}, Z_{ss})$, then $X_{ss}^\Delta = c(Y_{ss}^\Delta, Z_{ss}^\Delta)$ and $X_{ss}^\Delta = v(Y_{ss}^\Delta, Z_{ss}^\Delta)$.
- If $h(Y_{ss}, Z_{ss}) = \theta_p$ then $c(Y_{ss}^\Delta, Z_{ss}^\Delta) = 0$.

To understand the meaning of these restrictions, note that the first one states that if a model has an equation of the form $X_{ss} = Y_{ss}$, X_{ss} and Y_{ss} need to grow at the same rate along the balanced growth path. Similarly, the second restriction forces the two sides of the equation to have the same growth rate. The third expression consists of two terms; $X_{ss} = h(Y_{ss}, Z_{ss}) \pm g(Y_{ss}, Z_{ss})$ and forces them to grow at the same rate along the balanced growth path. The last condition requires $h(Y_{ss}, Z_{ss})$ to display no growth, as θ_p is a constant. The logic of the next expressions are similar:

Plus/Minus ($\pm$)

- If $X_{ss} \pm Y_{ss}$, then $X_{ss}^\Delta = Y_{ss}^\Delta$.
- If $X_{ss} \pm Y_{ss} \pm Z_{ss}$, then $X_{ss}^\Delta = Y_{ss}^\Delta$ and $X_{ss}^\Delta = Z_{ss}^\Delta$.
- If $X_{ss} \pm h(Y_{ss}, Z_{ss})$, then $X_{ss}^\Delta = c(Y_{ss}^\Delta, Z_{ss}^\Delta)$.
- If $X_{ss} \pm h^\pm(Y_{ss}, Z_{ss})$, then $X_{ss}^\Delta = c(Y_{ss}^\Delta, Z_{ss}^\Delta)$ and $X_{ss}^\Delta = v(Y_{ss}^\Delta, Z_{ss}^\Delta)$.
- If $h(Y_{ss}, Z_{ss}) \pm \theta_p$, then $g(Y_{ss}^\Delta, Z_{ss}^\Delta) = 0$.
- If $\theta_p \pm \theta_d$, then $\theta_p \pm \theta_d$.

The last rule allows us to keep track of parameters. Since a parameter is an object of an equation, we need to ensure that, when applying the relevant operators, they are properly accounted for.

Times (*)

- If $X_{ss} Y_{ss}$, then $X_{ss}^\Delta + Y_{ss}^\Delta$.
- If $X_{ss} Y_{ss} Z_{ss}$, then $X_{ss}^\Delta + Y_{ss}^\Delta + Z_{ss}^\Delta$.
- If $X_{ss} h(Y_{ss}, Z_{ss})$, then $X_{ss} + c(Y_{ss}^\Delta, Z_{ss}^\Delta)$.

---

[1] In a forward accumulation exercise, one first fixes the independent variable with respect to which the scaling is performed and then computes the trend of each sub-expression recursively.

- If $X_{ss}h^{\pm}(Y_{ss}, Z_{ss})$, then $c(Y_{ss}^{\Delta}, Z_{ss}^{\Delta}) = v(Y_{ss}^{\Delta}, Z_{ss}^{\Delta})$ and $X_{ss}^{\Delta} + c(Y_{ss}^{\Delta}, Z_{ss}^{\Delta})$.
- If $X_{ss}\theta_p$, then X_{ss}^{Δ}.
- If $\theta_p \cdot \theta_d$ then $\theta_p \cdot \theta_d$.

The last two rules imply that multiplying X_{ss} by a parameter leaves its growth rate unchanged, and that parameters do not grow.

Divide (/)

- If $\frac{X_{ss}}{Y_{ss}}$, then $X_{ss}^{\Delta} - Y_{ss}^{\Delta}$.
- If $\frac{\left(\frac{X_{ss}}{Y_{ss}}\right)}{Z_{ss}}$, then $X_{ss}^{\Delta} - Y_{ss}^{\Delta} - Z_{ss}^{\Delta}$.
- If $\frac{X_{ss}}{\left(\frac{Y_{ss}}{Z_{ss}}\right)}$, then $X_{ss}^{\Delta} - Y_{ss}^{\Delta} + Z_{ss}^{\Delta}$.
- If $\frac{X_{ss}}{h^{\pm}(Y_{ss}, Z_{ss})}$, then $c(Y_{ss}^{\Delta}, Z_{ss}^{\Delta}) = v(Y_{ss}^{\Delta}, Z_{ss}^{\Delta})$ and $X_{ss}^{\Delta} - c(Y_{ss}^{\Delta}, Z_{ss}^{\Delta})$.
- If $\frac{X_{ss}}{\theta_p}$, then X_{ss}^{Δ}.
- If $\frac{\theta_p}{\theta_d}$ then $\frac{\theta_p}{\theta_d}$.

Power (^)

- If $(X_{ss})^{\theta_p}$ then $\theta_p * X_{ss}^{\Delta}$.
- If $\theta_p^{Y_{ss}}$, then $Y_{ss}^{\Delta} = 0$, i.e. Y_t must be stationary.
- If $\theta_p^{h(Y_{ss}, Z_{ss})}$, then $c(Y_{ss}^{\Delta}, Z_{ss}^{\Delta}) = 0$, i.e. $h(Y_t, Z_t)$ must be a stationary.
- If $\theta_p^{\theta_d}$ then $\theta_p^{\theta_d}$.

Expression of the form $(X_{ss})^{Y_{ss}}$ or $(X_{ss})^{h(Y_{ss}, Z_{ss})}$ are not supported. This is because, for example, the first expression leads to a combination of two restrictions $Y_{ss}^{\Delta} = 0$ and $Y_{ss}X_{ss}^{\Delta}$ that prevent us from solving for the balanced growth path separately from the stationary steady state, as Y_{ss} appears in the system in (4). Situations of this type however are rare in the current wave of DSGEs.

Exponential (exp)

- If $e^{X_{ss}}$ then $X_{ss}^{\Delta} = 0$, i.e. X_t must be stationary.
- If $e^{h(Y_{ss}, Z_{ss})}$ then $c(Y_{ss}^{\Delta}, Z_{ss}^{\Delta}) = 0$, i.e. $h(Y_{ss}, Z_{ss})$ must be a stationary.
- If e^{θ_p} then e^{θ_p}.

Natural logarithm (log)

- If $log(X_{ss})$ then $X_{ss}^{\Delta} = 0$, i.e. X_t must be stationary.

- If $log\left(h(Y_{ss}, Z_{ss})\right)$ then $c(Y_{ss}^{\Delta}, Z_{ss}^{\Delta}) = 0$, i.e. $h(Y_{ss}, Z_{ss})$ must be stationary.

- If $log(\theta_p)$ then $log(\theta_p)$.

Example To illustrate how the rules work, suppose we want to find the restrictions provided by:

$$X_t \times Y_t + Z_t^{\theta_1} - Q_t. \tag{5}$$

Define steady state auxiliary variables as follows:

$$
\begin{aligned}
X_{ss} \times Y_{ss} &+ Z_{ss}^{\theta_1} - Q_{ss} \\
&= (w_1 \times w_2) + w_3^{\theta_1} - w_4 \\
&\equiv w_5 + w_6 - w_4 = w_7.
\end{aligned} \tag{6}
$$

where $w_5 = w_1 \times w_2$ and $w_6 = w_3^{\theta_1}$. Let $\dot{w}$ be the operator obtained applying the above rules. The forward accumulation step consists of the followings:

1. $w_1 = X_{ss}$ leads to $\dot{w}_1 = X_{ss}^{\Delta}$

2. $w_2 = Y_{ss}$ leads to $\dot{w}_2 = Y_{ss}^{\Delta}$

3. $w_3 = Z_{ss}$ leads to $\dot{w}_3 = Z_{ss}^{\Delta}$

4. $w_4 = Q_{ss}$ leads to $\dot{w}_4 = Q_{ss}^{\Delta}$

5. $w_5 = w_1 \times w_2$ leads to $\dot{w}_5 = \dot{w}_1 + \dot{w}_2$

6. $w_6 = w_3^{\theta_1}$ leads to $\dot{w}_6 = \theta_1 \dot{w}_3$

7. $w_7 = w_5 + w_6 - w_4$ leads to $\dot{w}_5 = \dot{w}_6$ and $\dot{w}_5 = \dot{w}_4$

To apply the rules, we need an initial condition. Since $w_1 = X_{ss}$, no rules applies, and we must normalize by creating a seed. We set $\dot{w}_1 = X_{ss}^{\Delta}$, i.e. applying the dot operator to X_{ss}, gives its growth rate. Then:

1. $\dot{w}_5 = \dot{w}_6$ gives $\dot{w}_1 + \dot{w}_2 = \theta_p \dot{w}_3$ or, $X_{ss}^{\Delta} + Y_{ss}^{\Delta} = \theta_p Z_{ss}^{\Delta}$.

2. $\dot{w}_5 = \dot{w}_4$ gives $\dot{w}_1 + \dot{w}_2 = \dot{w}_4$ or $X_{ss}^{\Delta} + Y_{ss}^{\Delta} = Q_{ss}^{\Delta}$.

Applying the above rules to all the equations present in a model give us L_1 restrictions.

3.2 Identify the non-stationary variables

To the L_1 restrictions found in the last section, we add L_2 equations of the form $A_{ss}^\Delta = \gamma$; that is, A_t has a drift equal to γ. This allows the identification of the non-stationary variables without knowing the features of the forcing process A_t, which is necessary when the unit root is endogenous. In the end, we have $L = L_1 + L_2$ constraints. This produces a system of equations linear in X_{ss}^Δ and A_{ss}^Δ, that is:

$$C(\theta) \begin{bmatrix} X_{ss}^\Delta \\ A_{ss}^\Delta \end{bmatrix} = \begin{bmatrix} C^X(\theta) & C^A(\theta) \\ 0 & I \end{bmatrix} \begin{bmatrix} X_{ss}^\Delta \\ A_{ss}^\Delta \end{bmatrix} = \begin{bmatrix} 0 \\ \gamma \end{bmatrix}, \tag{7}$$

This system can be solved if $rank(C(\theta)) = M + Q$. In some cases a solution can be found even when $rank(C(\theta)) < M + Q$, in which case some of the endogenous variables are unrestricted. To allow for this possibility, we constrain all unrestricted endogenous variables to have no growth in steady state; that is for any X^1 in this group; we set $(X^1)_{ss}^\Delta = 0$. If a solution to (7) exists, it gives us the balanced growth path for each value of γ. We use this solution to identify the R non-stationary variables.

3.3 Obtaining the G^i functions

From (7) it is also possible to identify the variables dependent on G^i functions. Let $\hat{C}(\theta)$ be the matrix consisting of the columns corresponding to the R non-stationary variables in $\begin{bmatrix} C^X(\theta) & C^A(\theta) \end{bmatrix}$. Generally, the number of rows of $(\hat{C}(\theta)) > R$, and thus have more equations than non-stationary variables. Applying Gaussian elimination to the rows of $\hat{C}(\theta)'$, produces the row echelon form:

$$C(\theta)^{echelon} = \begin{bmatrix} c(\theta)_{1,1}^{echelon} & \cdots & c(\theta)_{1,R}^{echelon} \\ 0 & \ddots & \vdots \\ 0 & 0 & c(\theta)_{R,R}^{echelon} \\ 0 & 0 & 0 \end{bmatrix}. \tag{8}$$

During the process, we record the first R linearly independent columns of $\hat{C}(\theta)'$. Since the columns of $\hat{C}(\theta)'$ represent a function, we can use this index to select the R linearly independent equations in R non-stationary endogenous variables. This gives the required G^i functions.

3.4 Representing the stationary system

After recording the non-stationary variables, we "divide through" the optimality conditions. Noticing that $Z_{t+1}^i = \frac{X_{t+1}^i}{H^i(A_t)} = X_{t+1}^i \Delta Z_{t+1}^i$, $Z_{t-1}^i = \frac{X_{t-1}^i}{H^i(A_t)} = \frac{X_{t-1}^i}{\Delta Z_t^i}$, $\frac{A_{t+1}^i}{A_t^i} = \Delta A_{t+1}^i$, $\frac{A_t^i}{A_t^i} = 1$, $\frac{A_t^i}{A_{t-1}^i} = (\Delta A_t^i)^{-1}$, we can substitute X_{t+1}^i with $X_{t+1}^i \Delta Z_{t+1}^i$, X_{t-1}^i with $\frac{X_{t-1}^i}{\Delta Z_t^i}$, A_{t+1}^i with ΔA_{t+1}^i, A_t^i with 1 and A_{t-1}^i with $(\Delta A_t^i)^{-1}$, whenever they appear. These equations together with the G^i functions will give us (3).

4 The model file language

In order to run the algorithm with the NB toolbox, one needs to write the equations of the model to a file with .nb (or .mod) extension. The file consists of six blocks, describing the endogenous and exogenous variables, the parameters, the model, the unit root processes and what to report.

endogenous

A list of the endogenous variables. They may appear with lags and leads in the model, but a maximum of one lead is imposed. Variables are separated by a space or starting a new line.

unitrootvars

A list of the variables that generate non-stationary dynamics. They can have lags and leads, but a maximum of one lead is imposed. Variables are separated by a space or starting a new line.

exogenous

A list of the exogenous variables. They cannot have lags or leads and are assumed to be white noise with unit standard deviation. Variables are separated by a space or stating a new line.

parameters

A list of the parameters. This is block is optional, as one could write parameter values directly into the equations. Parameters are separated by a space or starting a new line.

model

A list of the equations. Each equation must end with a semicolon and may span more than one line. It must be typed-in using the endogenous and the exogenous variable names, and the parameter names or numbers (hard-coded parameters). For lead or lags use varName(+1) and varName(-1).

reporting

A list of the variables to be reported. For example, although the consumption share does not appear in a model, one may want to compute its response function to shocks or other summary statistics. The reporting command allows to set variables which do not appear directly in the model. The expression consists of the endogenous variables and/or the parameters and any MATLAB (or owned MATLAB) function that acts on a double vector, and returns an output of the same dimension as the input. Each equation must start with a variable name, there should be an equal sign followed by an expression, and it must end with a semicolon; for example, cy = c/y; or csx = cumsum(x).

Note that the specification of processes of A_t must be included in the model declaration block in its non-stationary form. If A_t does not depend on the exogenous forcing variables, there is a deterministic trend in the model; otherwise a stochastic trend is assumed. The processes for A_t may also depend on the

endogenous variables. This way, the model language accommodates many different assumption about the drivers of the trend. If no `unitrootvars` command is used in the file, the toolbox assumes that all the shocks are stationary and solves the model with standard tools.

A number handy functions may be used to simplify in the model file declaration. For example, steady_state(M) returns the steady state of the variable M and bgp(M) returns its growth rate along the balanced growth path. Both these functions are used in the example in Section 5.2. The algorithm is implemented as an object oriented MATLAB code. A description of how the algorithm works is in the Appendix A.

5 Examples

To show that the algorithm is easy to use and produces reliable results, we consider three models. The first is a real business cycle (RBC) model with a unit root in labor augmenting productivity; the second is a version of the larger-scale New Keynesian (NK) model of Justiniano *et al.* (2011) with multiple unit roots; the third is a closed economy model with R&D generated endogenous labor augmenting productivity.

5.1 A RBC model

There is exogenous labor supply, endogenous capital accumulation, and δ is the capital depreciation rate. Production is Cobb-Douglas in capital and labor, and the labor augmenting term A_t is a unit root:

$$log(\Delta a_t) = (1 - \lambda)log(g) + \lambda log(\Delta a_{t-1}) + u_t. \tag{9}$$

where $\Delta a_t = A_t/A_{t-1}$, g is the long-run mean, λ is a persistence parameter, and $u \sim iid(0, \sigma^2)$. Preferences are logarithmic in consumption and agents discount the future at the rate β. The details of the model and the optimality conditions are in the Appendix B. We first show how to solve the model manually, and then implement the algorithm we propose.

5.1.1 Using a manual approach

Steps 1-3: Finding the balanced growth path; the non-stationary variables and the G^i functions.

With only one shock, output, investment, consumption, and capital all grow at the rate log(g). To verify the guess, we apply the rules of Section 3.1. The production function gives

$$Y_{ss}^\Delta = \gamma(A_{ss}^\Delta + L_{ss}^\Delta) + (1 - \gamma)K_{ss}^\Delta. \tag{10}$$

where γ is a share parameter. The capital accumulation equation and the resource constraint give:

$$K_{ss}^\Delta = I_{ss}^\Delta. \tag{11}$$

$$Y_{ss}^\Delta = C_{ss}^\Delta \tag{12}$$

$$Y_{ss}^{\Delta} = I_{ss}^{\Delta} \tag{13}$$

The Euler equation and the definition of the real rate give:

$$r_{ss}^{\Delta} = 0, \tag{14}$$

$$r_{ss}^{\Delta} = Y_{ss}^{\Delta} - K_{ss}^{\Delta} \tag{15}$$

Finally, because labor supply is inelastic, it must be the case that

$$L_{ss}^{\Delta} = 0. \tag{16}$$

These equations imply:

$$C_{ss}^{\Delta} = I_{ss}^{\Delta} = K_{ss}^{\Delta} = Y_{ss}^{\Delta} = A_{ss}^{\Delta} \equiv log(g), \tag{17}$$

Hence, for these five variables $H^i(A_t) = A_t$, and equations (10)-(13), (15) (16) determine the G^i functions.

Step 4: The stationary system

For any M_t, let $m_t = \frac{M_t}{H^m(A_t)}$ be its stationary version, and $\Delta m_t = exp(M_t^{\Delta}) = \frac{H^m(A_t)}{H^m(A_{t-1})}$ its growth rate. The equations of the stationary system are:

Production function:

$$y_t = L_t^{\gamma} \left(\frac{k_{t-1}}{\Delta k_t} \right)^{1-\gamma}. \tag{18}$$

Capital accumulation equation:

$$k_t = (1-\delta) \frac{k_{t-1}}{\Delta k_t} + i_t, \tag{19}$$

Market clearing condition:

$$y_t = c_t + i_t, \tag{20}$$

Euler equation:

$$\frac{E[c_{t+1} \Delta c_{t+1}]}{c_t} = \beta(1+r), \tag{21}$$

Definition of the real rate:

$$(1-\gamma) \frac{E[y_{t+1} \Delta y_{t+1}]}{k_t} = r + \delta. \tag{22}$$

(21), (18), (19) (20) determine the steady state of the stationary system:

$$r_{ss} = \frac{g}{\beta} - 1. \tag{23}$$

$$y_{ss} = \left(\frac{k_{ss}}{g} \right)^{(1-\gamma)}, \tag{24}$$

$$i_{ss} = \left(1 - \frac{1-\delta}{g} \right) k_{ss}, \tag{25}$$

11

$$c_{ss} = y_{ss} - i_{ss}, \text{ and} \tag{26}$$

Moreover, using (24) into (22) we get

$$k_{ss} = \left(\frac{r+\delta}{1-\gamma}\right)^{\left(-\frac{1}{\gamma}\right)} g. \tag{27}$$

The steady state for the five unknowns is the solution to these five equations.

To compute the linear approximation to the solution of the stationary system around the steady state, one can employ standard package such as DYNARE (Dynare (2021)), GENSYS (Sims (2010)) or the NB toolbox (Paulsen (2021)). With the linear approximate solution, interesting statistics such as impulse responses, variance or historical decompositions can be easily computed.

5.1.2 Using the automatic approach

Rather than proceeding manually, we write the equations of the non-stationary model to a file and let a software take care of the rest. The file is as follows:

```
endogenous
c dA i k l r y

exogenous
u

unitrootvars
A

parameters
beta  delta g gamma lambda std_u

model
    c(+1)/c             = beta*(1 + r);
    l                   = 1;
    y                   = (A*l)^gamma * k(-1)^(1-gamma);
    (1-gamma)*y(+1)/k   = r + delta;
    k                   = (1-delta)*k(-1) + i;
    y                   = c + i;
    dA                  = A/A(-1);
    A/A(-1)             = g^(1-lambda)*(A(-1)/A(-2))^lambda*exp(std_u*u);
```

```
reporting

    A         = exp(cumsum(log(dA) - log(steady_state(dA)))); % level variables

    C         = c*A;     I  = i*A;      K  = k*A;     Y = y*A;

    c_log_dev = exp(log(c) - log(steady_state(c)));  % deviations  from steady state

    i_log_dev = exp(log(i) - log(steady_state(i)));

    k_log_dev = exp(log(k) - log(steady_state(k)));

    r_dev     = r - steady_state(r);

    y_log_dev = exp(log(y) - log(steady_state(y)));
```

With this file (saved as non_stationary.nb), the NB commands needed to stationarize the system and to compute impulse responses:

```
modelNS = nb_dsge('nb_file','non_stationary.nb'); %Read the model file

modelNS = set(modelNS,'name','Stationarize automatically'); % Name it

param       = struct( );     % Assign parameter values
param.g     = 1.03;   param.gamma  = 0.60;  param.delta  = 0.10;
param.beta  = 0.97;  param.lambda = 0;    param.std_u  = 0.01;
modelNS     = assignParameters(modelNS,param);

% Find the balanced growth path, (steps 1-3 of the algorithm):
modelNS  = solveBalancedGrowthPath(modelNS);

% Make  the model  stationary (step 4 of the algorithm):
modelNS = stationarize(modelNS)

% Find the steady state and return it as  a cell matrix:
modelNS = checkSteadyState(modelNS,...
    'solver',                 'fsolve',...
    'steady_state_solve',    true,...
    'steady_state_default', @ones);
ss = getSteadyState(modelNS)

% Return the balanced growth path solution as a cell matrix:
bgp = getBalancedGrowthPath(modelNS)

% Obtain the linear solution: y(t) = A y(t-1) + B eps(t)
% and  compute  impulse responses
modelNS = solve(modelNS);

% Compute and plot  impulse responses
% Note modelS object represents the model stationarized manually.
[irfs,~,plotter] = irf([modelNS,modelS],...
   'variables',[modelNS.dependent.name(1:7),modelNS.reporting(:,1)'],...
   'settings',{'legBox','off','legFontSize',18,'subPlotSize',[4,3],...
               'figureTitle',false});
nb_graphInfoStructGUI(plotter)
```

The stationary model file produced by these commands is in Appendix B. If a user wants to save the stationary model for later purposes or to use in other packages, it is possible to write it to a file using:

```
writeModel2File(modelNS,'stationarized.nb')
```

We plot the dynamics induced by a one standard deviation increase in the labor-augmenting shock in the manual and automated solutions in Figure 1; the top part has the stationary variables, the bottom part the level variables. If the automated solution is accurate, the responses should be identical.
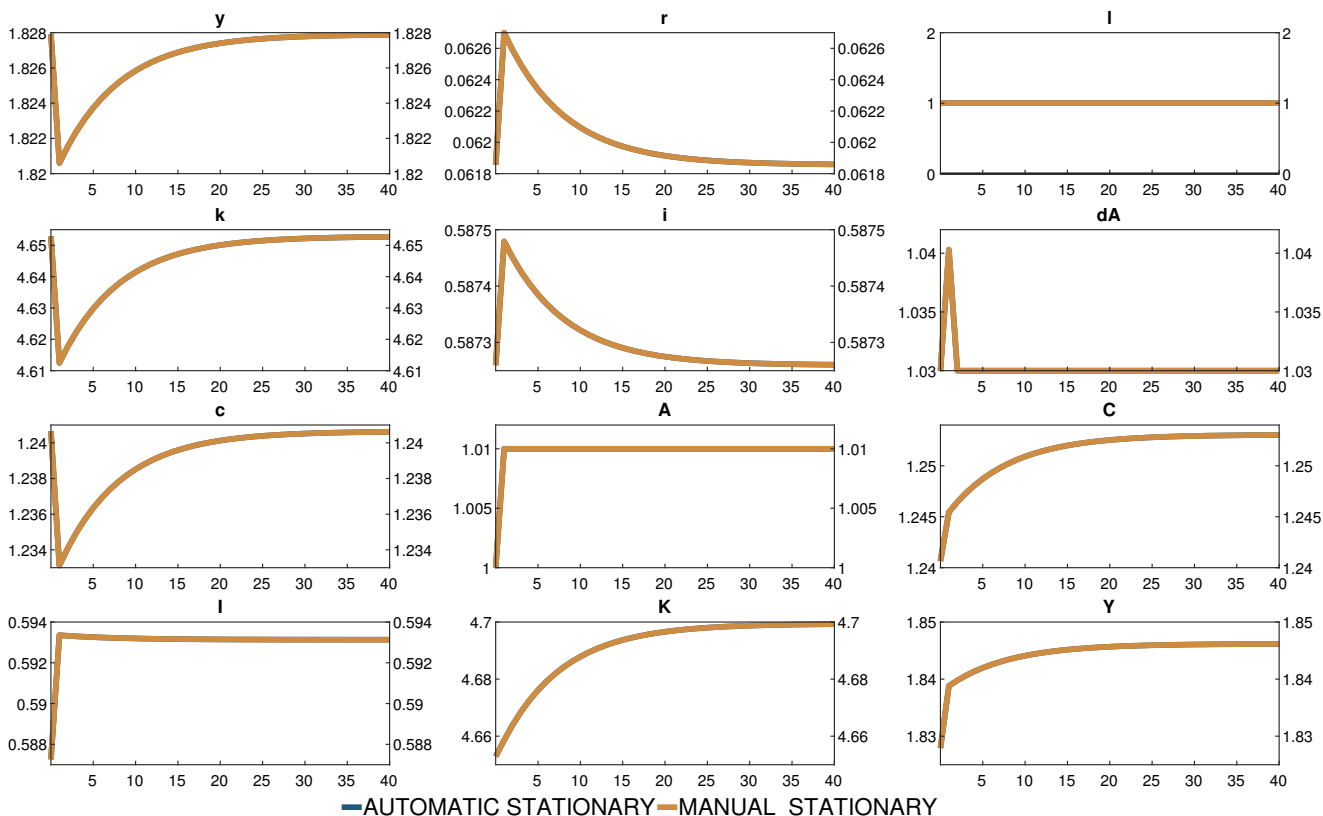

Figure 1: Impulse responses. A is the labour augmenting process. y, r, l, k, i, dA and c are the stationary variables in log deviation from the steady state; C, I, K and Y are the non-stationary levels of the variables.

The two impulse responses are clearly indistinguishable. As the economy becomes permanently more productive, output (Y), consumption (C), investment (I) and capital (K) jump on impact and slowly reach the new long run level. Because the expected output to capital ratio increases on impact, the real interest rate (r) rises and this induces a fall in transitory consumption (c). As the economy moves to the

14

new steady state the real interest rate falls and transitory variables return to their original levels.

5.2 A New Keynesian model

This section compares the manual and the automated decision rules of a slightly modified version of the Justiniano *et al.* (2011) model and studies the consequences of assuming unit roots in different shocks. The model allows us to illustrate how the algorithm works when the trend path is driven by multiple disturbances. The model deviates from Justiniano *et al.* (2011) in three ways: we assume Rotemberg rather than Calvo prices and wages adjustments; we use different functional forms for capital utilization and for investment-adjustment costs; and we set government purchases of goods and services to zero.

There are six types of agents: final and intermediate good producing firms, consumers, investment and capital producers, and entrepreneurs. Their problems and the optimality conditions are in the Appendix C. The model features nine disturbances, two of which are assumed to be non-stationary: Z_t, the labor-augmenting technology process, and Υ_t, the investment-specific technology process. Z_t grows at the gross rate $\pi_t^z = \frac{Z_t}{Z_{t-1}}$, while Υ_t grows at the gross rate $\pi_t^\Upsilon = \frac{\Upsilon_t}{\Upsilon_{t-1}}$. The law of motion of all the disturbances is also described in the Appendix C.

Let P_t^X be the nominal price of the variable X in period t. The consumption good is the numeraire and its price is P_t, which will be non-stationary. Let $\pi_t = \frac{P_t}{P_{t-1}}$ be the inflation rate, W_t the nominal wage, $R_t^X \equiv 1 + r_t^X$ the gross interest rate in sector or variable X and r_t^X the net rate of interest. All other variables are expressed in real terms, unless otherwise stated. Finally, let $\widetilde{X}_t$ denote the stationary version of X and $\widetilde{X}_{ss}$ its steady state.

5.2.1 Computing the stationary system manually

Justiniano *et al.* (2011) state that $Z_t \Upsilon_t^{\frac{\alpha}{1-\alpha}}$ is the balanced growth path for this economy. To show that this is indeed the case, we scale the optimality conditions of by this factor and show that they still hold after the transformation. From the final and intermediate goods sectors' conditions we get:

i) Final good production function:
$$\widetilde{A}_t = \widetilde{Q}_t. \tag{28}$$

ii) Pricing of final good:
$$\widetilde{P}_t = \widetilde{P}_t^Q. \tag{29}$$

iii) Intermediate goods production function:
$$\widetilde{Q}_t = (z_t^L L_t)^{1-\alpha} \left(\overline{\widetilde{K}}_t \right)^\alpha \tag{30}$$

iv) Wage and nominal rate definitions:
$$\widetilde{W}_t \equiv \frac{W_t}{P_t \Upsilon_t^{\frac{\alpha}{1-\alpha}} Z_t}; \ \ \widetilde{R}_{K,t} \equiv \frac{\Upsilon_t R_{K,t}}{P_t} \tag{31}$$

v) Labor demand function:

$$L_t = (1 - \alpha) \frac{\widetilde{MC}_t}{\widetilde{W}_t} \widetilde{Q}_t. \tag{32}$$

vi) Capital demand function:

$$\widetilde{\overline{K}}_t = \alpha \frac{\widetilde{MC}_t}{\widetilde{R}_t^K} \widetilde{Q}_t. \tag{33}$$

vii) Using $P_t^Q = P_t^Q(n)$ and $\pi_t^Q \equiv \frac{P_t^Q}{P_{t-1}^Q}$, the cost of adjusting prices is

$$\gamma_{PQ,t} = \frac{\phi^{PQ}}{2} \left[\frac{\pi_t^Q}{\pi_{t-1}^Q} - 1 \right]^2. \tag{34}$$

viii) The Euler equation for intermediate firms is:

$$\widetilde{Q}_t - \theta_t^H \widetilde{Q}_t + \widetilde{MC}_t \theta_t^H \frac{\widetilde{Q}_t}{\widetilde{P}_t^Q} - \phi^{PQ} \left[\frac{\pi_t^Q}{\pi_{t-1}^Q} - 1 \right] \frac{\pi_t^Q}{\pi_{t-1}^Q} \widetilde{Q}_t$$
$$+ E_t \left\{ \Lambda \phi^{PQ} \left[\frac{\pi_{t+1}^Q}{\pi_t^Q} - 1 \right] \frac{(\pi_{t+1}^Q)^2}{\pi_t^Q} \widetilde{Q}_{t+1} \left(\pi_{t+1}^\Upsilon \right)^{\frac{\alpha}{1-\alpha}} \pi_{t+1}^z \right\} = 0. \tag{35}$$

The first order conditions for the investment and capital producer give:

ix) Production function for investment goods:

$$\widetilde{I}_t = \widetilde{Y}_t^I. \tag{36}$$

x) Investment price:

$$\widetilde{P}_t^I = 1. \tag{37}$$

xi) Production function for capital goods:

$$\widetilde{K}_t^{new} = z_{I,t} \left(1 - S \left(\frac{\widetilde{I}_t}{\widetilde{I}_{t-1}} \right) \right) \widetilde{I}_t. \tag{38}$$

xii) Optimality condition for investments:

$$\left[\Lambda \frac{1}{\pi_{t+1}^\Upsilon} \widetilde{P}_{t+1}^K z_{I,t+1} S_2' \left(\frac{\widetilde{I}_{t+1}}{\widetilde{I}_t} \right) \widetilde{I}_{t+1} \right] -$$
$$\widetilde{P}_t^K z_{I,t} \left[1 - S \left(\frac{\widetilde{I}_t}{\widetilde{I}_{t-1}} \right) - S_1' \left(\frac{\widetilde{I}_t}{\widetilde{I}_{t-1}} \right) \widetilde{I}_t \right] - \widetilde{P}_t^I = 0 \tag{39}$$

xiii) Investment adjustment costs:

$$S \left(\frac{\widetilde{I}_t}{\widetilde{I}_{t-1}} \right) = \frac{\phi_{I1}}{2} \left[\frac{\widetilde{I}_t}{\widetilde{I}_{t-1}} \left(\pi_t^\Upsilon \right)^{\frac{1}{1-\alpha}} \pi_t^z - \left(\pi_{ss}^\Upsilon \right)^{\frac{1}{1-\alpha}} \pi_{ss}^z \right]^2. \tag{40}$$

16

and thus

$$S_1'\left(\frac{\widetilde{I}_t}{\widetilde{I}_{t-1}}\right)\widetilde{I}_t = \frac{\phi_{I1}\left[\frac{\widetilde{I}_t}{\widetilde{I}_{t-1}}\left(\pi_t^{\Upsilon}\right)^{\frac{1}{1-\alpha}}\pi_t^z - \left(\pi_{ss}^{\Upsilon}\right)^{\frac{1}{1-\alpha}}\pi_{ss}^z\right]}{\frac{\widetilde{I}_t}{\widetilde{I}_{t-1}}\left(\pi_t^{\Upsilon}\right)^{\frac{1}{1-\alpha}}\pi_t^z}. \tag{41}$$

$$S_2'\left(\frac{\widetilde{I}_t}{\widetilde{I}_{t-1}}\right)\widetilde{I}_t = -\frac{\phi_{I1}\left[\frac{\widetilde{I}_t}{\widetilde{I}_{t-1}}\left(\pi_t^{\Upsilon}\right)^{\frac{1}{1-\alpha}}\pi_t^z - \left(\pi_{ss}^{\Upsilon}\right)^{\frac{1}{1-\alpha}}\pi_{ss}^z\right]}{\left(\frac{\widetilde{I}_t}{\widetilde{I}_{t-1}}\left(\pi_t^{\Upsilon}\right)^{\frac{1}{1-\alpha}}\pi_t^z\right)^2}. \tag{42}$$

The first order conditions for the households and the entrepreneurs give:

Xiv) Marginal utility of consumption:

$$\left(\Upsilon_t^{\frac{\alpha}{1-\alpha}}Z_t\right)u'(C_t) \equiv \widetilde{u}'\left(\widetilde{C}_t\right) = z_t^u\left[\frac{\widetilde{C}_t - \widetilde{C}_{t-1}\left(\frac{b^c}{(\pi_t^{\Upsilon})^{\frac{\alpha}{1-\alpha}}\pi_t^z}\right)}{\left(1 - \frac{b^c}{(\pi_{ss}^{\Upsilon})^{\frac{\alpha}{1-\alpha}}\pi_{ss}^z}\right)}\right]^{-1}. \tag{43}$$

xv) Marginal disutility of labor:

$$v'(L_t) = \left[\frac{L_t(j) - b^l L_{t-1}}{1 - b^l}\right]^{\zeta}. \tag{44}$$

xvi) The stochastic discount factor:

$$\Lambda_{t,t+i} \equiv \beta^i \frac{\rho_{t+1}\widetilde{u}'\left(\widetilde{C}_{t+i}\right)}{\rho_t\widetilde{u}'\left(\widetilde{C}_t\right)}\frac{1}{\pi_{t+i}}\frac{1}{\left(\pi_{t+i}^{\Upsilon}\right)^{\frac{\alpha}{1-\alpha}}\pi_{t+i}^z}, \tag{45}$$

Then the one-period ahead stochastic discount factor is then

$$\Lambda_{t,t+1} \equiv \beta \frac{\rho_{t+1}\widetilde{u}'\left(\widetilde{C}_{t+1}\right)}{\rho_t\widetilde{u}'\left(\widetilde{C}_t\right)}\frac{1}{\pi_{t+1}}\frac{1}{\left(\pi_{t+1}^{\Upsilon}\right)^{\frac{\alpha}{1-\alpha}}\pi_{t+1}^z}. \tag{46}$$

xvii) Optimality condition for bond holdings:

$$E_t\left[\Lambda_{t,t+1}\right]R_t = 1, \tag{47}$$

xviii) Labor supply equation:

$$\widetilde{W}_t = \psi_t MRS(L_t, \widetilde{C}_t)\left[\begin{array}{c}[\psi_t - 1][1 - \gamma_t] \\ +\phi^W\frac{\pi_t^W}{\pi_{t-1}^W}\left(\frac{\pi_t^W}{\pi_{t-1}^W} - 1\right) \\ -E\left[\Lambda\phi^W\frac{L_{t+1}}{L_t}\frac{\pi_{t+1}^W}{\pi_t^W}\left(\frac{\pi_{t+1}^W}{\pi_t^W} - 1\right)\right]\end{array}\right]^{-1}. \tag{48}$$

where

$$MRS(L_t, C_t) = \frac{\Upsilon_t^{\frac{\alpha}{1-\alpha}}Z_t v'(L_t)}{\widetilde{u}'\left(\widetilde{C}_t\right)} = \Upsilon_t^{\frac{\alpha}{1-\alpha}}Z_t MRS(L_t, \widetilde{C}_t). \tag{49}$$

xix) Wage adjustment equation:

$$\gamma_t \equiv \frac{\phi^W}{2} \left[\frac{\pi_t^W}{\pi_{t-1}^W} - 1 \right]^2. \tag{50}$$

xx) Optimality condition for capital:

$$\widetilde{P}_t^K = E_t \left[\Lambda \pi_{t+1} \left(\begin{array}{c} \frac{1}{\pi_{t+1}^\Upsilon} \widetilde{P}_{t+1}^K (1 - \delta) \\ + \frac{1}{\pi_{t+1}^\Upsilon} \widetilde{R}_{K,t+1} U_{t+1} - \frac{1}{\pi_{t+1}^\Upsilon} \widetilde{\gamma} (U_{t+1}) \end{array} \right) \right]. \tag{51}$$

xxi) Optimality condition for capital utilization:

$$\widetilde{R}_{K,t} = \widetilde{\gamma}' (U_t), \tag{52}$$

where we have used that

$$\widetilde{\gamma} (U_t) \equiv \Upsilon_t \gamma (U_t) = \frac{\widetilde{R}_{ss}^K}{\phi_u} \left[e^{\phi_u (U_t - 1)} - 1 \right], \tag{53}$$

$$\widetilde{\gamma}' (U_t) \equiv \Upsilon_t \gamma' (U_t) = \widetilde{R}_{K,ss} e^{\phi_u (U_t - 1)}. \tag{54}$$

xxii) Effective capital definition:

$$\widetilde{\overline{K}}_t = U_t \frac{\widetilde{K}_{t-1}}{\left(\pi_t^\Upsilon \right)^{\frac{1}{1-\alpha}} \pi_t^z}. \tag{55}$$

xxiii) Physical capital accumulation equation:

$$\widetilde{K}_t = \frac{(1 - \delta) \widetilde{K}_{t-1}}{\left(\pi_t^\Upsilon \right)^{\frac{1}{1-\alpha}} \pi_t^z} + \widetilde{K}_t^{new}. \tag{56}$$

xxiv) Final goods market clearing:

$$\widetilde{A}_t = \widetilde{C}_t + \widetilde{Y}_t^I. \tag{57}$$

xxv) Final goods inflation:

$$\pi_t \equiv \frac{P_t}{P_{t-1}}. \tag{58}$$

xxvi) Intermediate goods inflation:

$$\pi_t^Q = \pi_t \frac{\widetilde{P}_t^Q}{\widetilde{P}_{t-1}^Q}. \tag{59}$$

xxvii) Wage inflation:

$$\pi_t^W = \frac{\widetilde{W}_t}{\widetilde{W}_{t-1}} \pi_t \pi_t^z \left(\pi_t^\Upsilon \right)^{\frac{\alpha}{1-\alpha}}. \tag{60}$$

xxviii) Output definition:

$$\widetilde{Y}_{NAT,t} = \widetilde{A}_t. \tag{61}$$

xxix) Output growth definition:

$$\triangle \widetilde{Y}_{NAT,t} = \frac{\widetilde{Y}_{NAT,t}}{\widetilde{Y}_{NAT,t-1}} \pi_t^z \left(\pi_t^\Upsilon \right)^{\frac{\alpha}{1-\alpha}} . \tag{62}$$

A file with these equations and a set of instructions used to solve the system with the NB toolbox are in the Appendix D.

5.2.2 Computing the stationary system automatically

The steps are the same as in the RBC example. First, we write the equations of the non-stationary model to a file and save it with name jpt_non_stationary.nb. This file is reproduced in the Appendix E together with the commands needed to make the model stationary and compute impulse responses. The resulting file with the stationary model is also reproduced in the Appendix F. To check for the accuracy of the automated solution, we compare impulse responses to an investment-specific technology shock in the stationary version of the model computed manually and automatically and plot them in figure 2. The two responses are identical also in this case.

An investment-specific shock permanently raises consumption, investment, and output although the level of consumption and level of output temporarily move in different directions. As an investment unit is permanently transformed into more capital, investment, consumption and output as a deviation from the steady state temporarily fall and converge slowly. The responses of stationary variables are persistent because price adjustment costs are important. Hours also fall but temporarily while price inflation and wage inflation initially fall and then rebound as demand for transitory investment builds up. Finally, given the Taylor rule, the dynamics of the interest rate track the dynamics of inflation along the adjustment path.

It is instructive to analyze the G^i functions produced. They are characterized by 18 equations:

$$A_t^\triangle = Q_t^\triangle, \tag{63}$$

$$T_t^\triangle - \alpha \bar{K}_t^\triangle = (1 - \alpha) Z_t^\triangle, \tag{64}$$

$$\bar{K}_t^\triangle + R^K{}_t^\triangle = T_t^\triangle, \tag{65}$$

$$\left(\frac{W}{P} \right)_t^\triangle = T_t^\triangle, \tag{66}$$

$$I_t^\triangle - \Upsilon_t^\triangle = Y^I{}_t^\triangle, \tag{67}$$

$$\left(\frac{P^I}{P} \right)_t^\triangle = -\Upsilon_t^\triangle, \tag{68}$$

$$K^{new}{}_t^\triangle = I_t^\triangle, \tag{69}$$

19
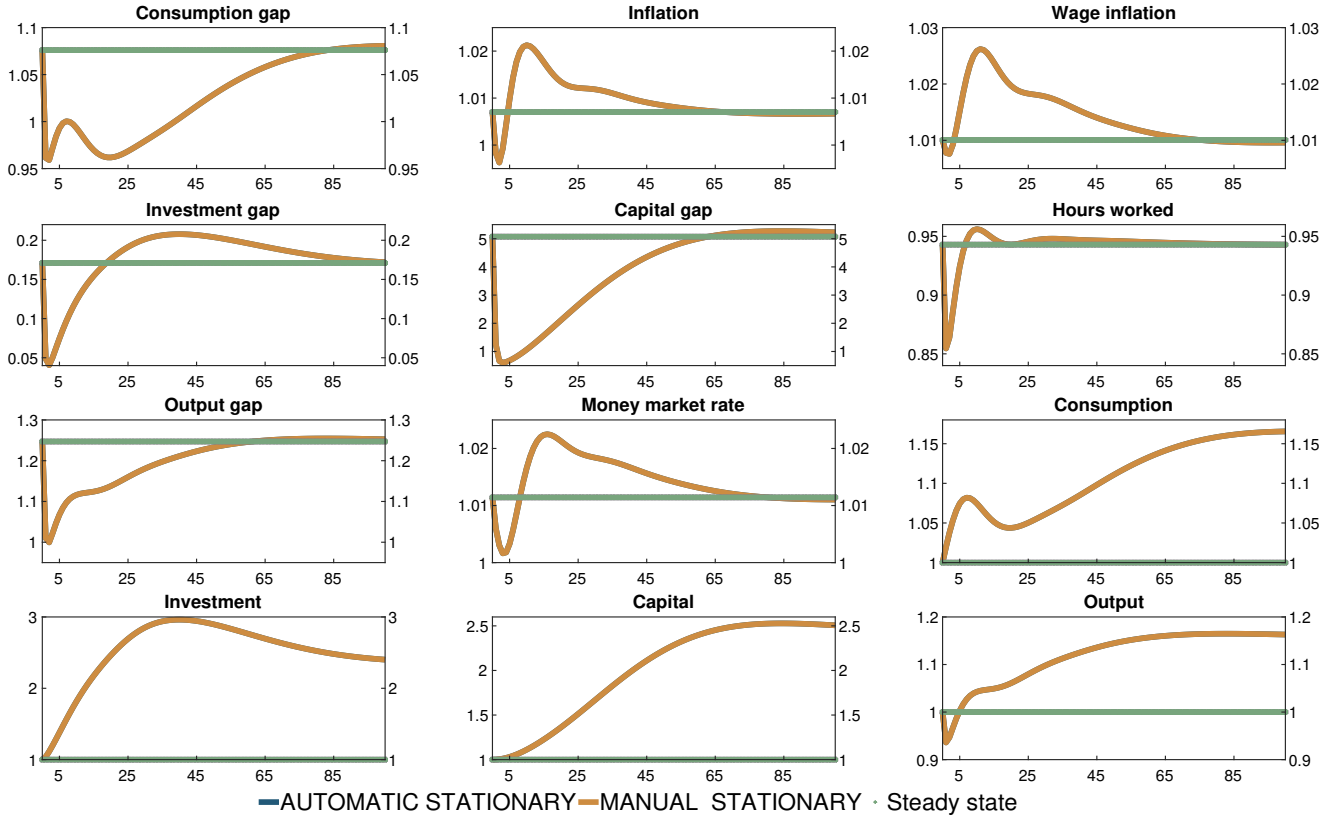

Figure 2: Responses of variables to an temporary shock to investment-specific technology. The green line gives the steady state/inital value.

$$\left(\frac{P^K}{P}\right)_t^{\triangle} = \left(\frac{P^I}{P}\right)_t^{\triangle}, \tag{70}$$

$$C_t^{\triangle} - u'\left(C\right)_t^{\triangle} = 0, \tag{71}$$

$$\left(\frac{W}{P}\right)_t^{\triangle} = \left(\frac{v'\left(L\right)}{u'\left(C\right)}\right)_t^{\triangle}, \tag{72}$$

$$\left(\frac{v'\left(L\right)}{u'\left(C\right)}\right)_t^{\triangle} = -u'\left(C\right)_t^{\triangle}, \tag{73}$$

$$\left(\frac{P^K}{P}\right)_t^{\triangle} = R^{K\triangle}_t, \tag{74}$$

$$\left(\frac{P^K}{P}\right)_t^{\triangle} = \gamma\left(U\right)_t^{\triangle}, \tag{75}$$

$$R^{K\triangle}_t = \gamma'(U)^{\triangle}_t, \tag{76}$$

$$K^{\triangle}_t = K^{new\triangle}_t, \tag{77}$$

$$\bar{K}^{\triangle}_t = K^{\triangle}_t, \tag{78}$$

$$A^{\triangle}_t = C^{\triangle}_t, \tag{79}$$

$$Y^{\triangle}_t = A^{\triangle}_t. \tag{80}$$

(63)-(64) come from the final good and the intermediate production functions, (65)-(66) from the intermediate producer conditions, (67)-(68) from the investment good production function and optimization, (69)-(70) from capital production and optimization, (71)-(78) from the consumer optimality conditions, while (79)-(80) are obtained from market clearing and the resource constraint.

Recall that these equations characterize the trending variables. Note that, while capital, its real rate and the real wage are on the list, hours are not. Also, since the relative price of capital is trending, the marginal rate of substitution between leisure and consumption is also trending. We contrast these facts next with those implied by a model with unit root in preferences.

5.2.3 Changing the location of the unit root

To investigate the consequences of assuming unit roots in different disturbances, we let the preference shock, rather than the investment-specific technology shock, be a unit root process. In practice, this requires removing Υ_t from the list of processes generating non-stationary dynamics, and adding X_t to it, where X_t is the preference shock, entering the utility as follows

$$u(C_t(j)) = X_t z^u_t \left(1 - \frac{b^c}{\pi^z_{ss}}\right) \ln\left[\frac{C_t(j) - b^c C_{t-1}}{\left(1 - \frac{b^c}{\pi^z_{ss}}\right)}\right], \tag{81}$$

The model file is in the Appendix G. The automatically stationarized file in the Appendix I.

Clearly, when different disturbances feature unit root, the G^i function will generally change as different variables display trending behavior. Thus, a comparison of the G^i functions allows a researcher to understand the specification that is more likely to be compatible with the data. When the preference shock features a unit root equations (63), (69), (72), (77), (78), (79) and (80) are unchanged. Equations (67),(68), (70), (74)-(76) are no longer relevant. From the intermediate production function, we now have:

$$(\alpha - 1)L^{\triangle}_t + T^{\triangle}_t - \alpha\bar{K}^{\triangle}_t = (1 - \alpha)Z^{\triangle}_t, \tag{82}$$

while equations (65), (66) and (71) become

$$\bar{K}^{\triangle}_t + R^{K\triangle}_t = T^{\triangle}_t, \tag{83}$$

21

Table 1 Balanced growth, selected variables.

	Model with a unit root in investment technology	Model with a unit root in preferences
C	1.0030	1.0029
I	1.0090	1.0029
K	1.0090	1.0029
L	1.0000	1.0011
Y	1.0030	1.0029
$\frac{P^I}{P}$	0.9941	1.0000
W	1.0030	1.0018

$$L_t^{\triangle} + \left(\frac{W}{P}\right)_t^{\triangle} = T_t^{\triangle}, \tag{84}$$

$$C_t^{\triangle} - u'(C)_t^{\triangle} = X_t^{\triangle}. \tag{85}$$

Compared with the version with investment specific unit root, the return on capital is now stationary while hours worked are trending to allow for the permanent increase in preferences for consumption. As a consequence, the marginal utility of labor is also trending and the marginal rate of substitution is also affected because with trending hours, real wages do not grow at same rate as output.

$$\zeta L_t^{\triangle} = v'(L)_t^{\triangle}, \tag{86}$$

$$\left(\frac{v'(L)}{u'(C)}\right)_t^{\triangle} = v'(L)_t^{\triangle} - u'(C)_t^{\triangle}. \tag{87}$$

Finally, the market clearing condition imply an additional restriction:

$$A_t^{\triangle} = Y^I{}_t^{\triangle}. \tag{88}$$

We report the growth rates of few variables of the model in table 1. In the economy with investment-specific technology shocks, investment and capital increase faster than output over time, as the real price of investment decreases over time, while this is not the case in the economy with unit roots in preferences. Thus, this set of facts can be used to select which specification is more in line with the data. Alternatively, suppose that the labor share is of interest. If, in the data, it is trending and hours are stationary, which happens in US, France, Germany and Canada (see e.g. Canova and Matthes (2021)) then a model with unit root in investment-specific shocks should be preferred, as it implies trending output and stationary hours. If, on the other hand, the labor share and hours are both trending, as it happens, for example, in the UK, then a model with unit root in preferences is more appealing, as both output and hours display a

Table 2 Steady states and unconditional variances, selected variables.

$1 + r_t$	0.2721	0.2817

unit root without being cointegrated. In general, with stylized growth facts in hand, one can choose which disturbances should be made non-stationary, and this helps to improve the specification of the model.

Table 2 reports the steady-state values and the unconditional variances of two stationary versions of the model for selected variables. Clearly, the steady states generally differ. For a given set of parameters, average consumption, investment, hours and output are typically higher in the economy with a unit root in preference, while wages and the nominal rate are smaller. This is because preferences and technologies are simultaneously trending. As a consequence, the model with a unit root in preference also displays higher variability. For example, capital is almost two and half times and consumption is one fourth more volatile in this case.

Impulse responses to a labor augmenting shock in the two systems are in figure 3. While the growth rates and the steady states of the two models differ, the dynamics in response to other shocks present in the model should be qualitatively independent to the location of the other unit roots. Indeed, the responses in the two systems are similar. The main quantitative difference comes from the fact already mentioned that capital grows faster in the economy with investment specific unit roots and this produces a different steady state for consumption, investment, and output.
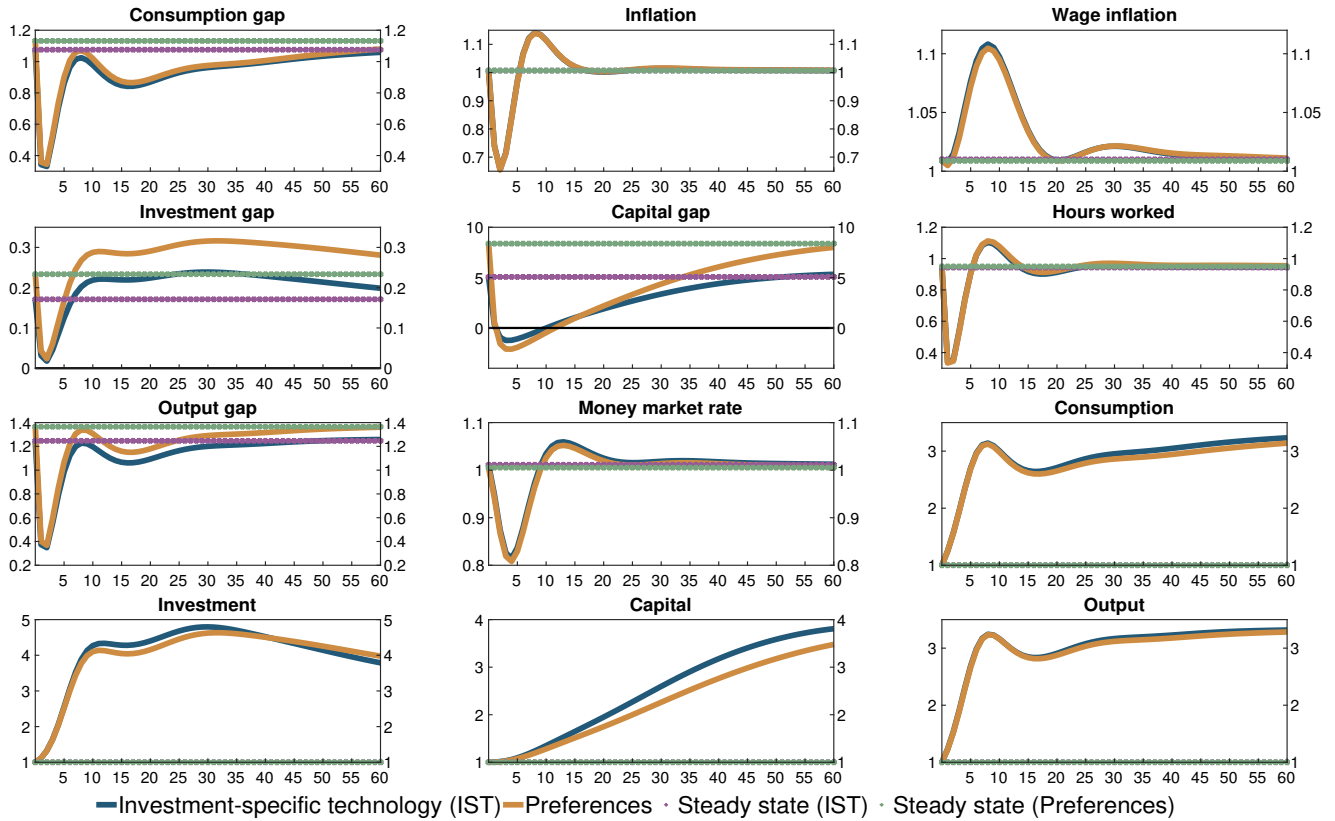

Figure 3: Responses to a labor augmenting technology shock. The purple line gives the steady state/inital value in the economy with investment-specific technology, while the green gives the steady state/inital value in the economy with unit roots in preferences.

5.3 Models with endogenous unit roots

As mentioned one of the advantages of our approach relative to existing ones, is that it can be employed also in models where the process responsible for the growth dynamics is endogenous rather than exogenous.

To illustrate that indeed the mechanical approach works in this case, we consider a closed economy model with exogenous labor supply, endogenous physical and R&D capital accumulation; preferences are logarithmic in consumption. The production function is

$$Y_t = (A_{t-1}L_t)^\gamma K_{t-1}^{1-\gamma}, \tag{89}$$

where Y_t is output, $L_t = 1$ is labor, K_t is physical capital, A_t is R&D capital and γ is the labor share.

Physical capital accumulates according to

$$K_t = (1 - \delta)K_{t-1} + I_t, \tag{90}$$

where I_t is physical investment and δ the depreciation rate. The representative household maximizes

$$E\left[\sum_{s=0}^{\infty} \beta^s U(C_{t+s})\right], \tag{91}$$

where β is the discount factor, subject to (89), (90) and the constraint

$$Y_t + B_t + P_t^A(1 - \delta^{RD})A_{t-1} = C_t + I_t + (1 + r_{t-1})B_{t-1} + P_t^A A_t + T_t, \tag{92}$$

where B_t are one period bond, T_t are the lump-sum taxes and P_t^A the relative price of R&D capital and δ^{RD} is the depreciation rate of R&D capital. Optimization implies:

$$E\left[\beta\frac{U'(C_{t+1})}{U(C_t)}\right](1 + r_t) = 1, \tag{93}$$

$$r_t = (1 - \gamma)\frac{E[Y_{t+1}]}{K_t} - \delta, \tag{94}$$

$$1 + r_t = E\left[\frac{P_{t+1}^A}{P_t^A}(1 - \delta^{RD}) + \frac{1}{P_t^A}\gamma\frac{Y_{t+1}}{A_t}\right]. \tag{95}$$

A R&D capital producer maximizes profits by choice of investment S_t

$$max_{\{S_t\}}\left[P_t^A A_t - P_t^A(1 - \delta^{RD})A_{t-1} - (1 - s_t^{RD})S_t\right], \tag{96}$$

subject to the R&D accumulation equation

$$A_t = \left[1 - \delta^{RD} + \upsilon\left(\frac{S_t}{A_t}\right)e^{u_t}\right]A_{t-1}, \tag{97}$$

where $\upsilon(.)$ is a function on the form

$$\upsilon\left(\frac{S_t}{A_t}\right) = g + \frac{\theta}{1 - \frac{1}{\zeta}}\left(\frac{S_t}{A_t}\right)^{1-\frac{1}{\zeta}}. \tag{98}$$

We assume $u_t \sim iid(0, \sigma^2)$. The R&D government subsidy s_t^{RD} is stochastic and follows a AR(1) process:

$$log(s_t^{RD}) = (1 - \lambda)log(s_{ss}^{RD}) + \lambda log(s_{t-1}^{RD}) + \epsilon_t. \tag{99}$$

The optimality condition for R&D capital producer is:

$$P_t^A\frac{A_{t-1}}{A_t}\theta\left(\frac{S_t}{A_t}\right)^{-\frac{1}{\zeta}}e^{u_t} = 1 - s_t^{RD}. \tag{100}$$

The government finances R&D subsidies $s_t^{RD} S_t$ using lump-sump taxes T_t and issuing one period real bonds B_t. The budget constraint is

$$B_t - (1 + r_{t-1})B_{t-1} + T_t = s_t^{RD} S_t, \tag{101}$$

(93)-(95) , (89), (90), (97) , (99), (100), (101) determine the equilibrium.

In this model both u_t and s_t^{RD} are stationary but A_t is a unit root with endogenous drift. Applying the rules of Section 3 one finds that output, consumption, physical investment and physical capital, R&D investment and R&D capital all grow at the same rate which is given by $(1 - \delta^{RD} + \upsilon(s_{ss}))$, where $s_{ss} = \frac{S^{ss}}{A^{ss}}$. Hence for these six variables $H^i(A_t) = A_t$, and the G^i functions are given by

$$Y_{ss}^{\Delta} = \gamma(A_{ss}^{\Delta} + L_{ss}^{\Delta}) + (1 - \gamma)K_{ss}^{\Delta}. \tag{102}$$

$$A_{ss}^{\Delta} = log(1 - \delta^d + \upsilon(s_{ss})). \tag{103}$$

$$K_{ss}^{\Delta} = I_{ss}^{\Delta}. \tag{104}$$

$$Y_{ss}^{\Delta} = C_{ss}^{\Delta} \tag{105}$$

$$r_{ss}^{\Delta} = 0, \tag{106}$$

$$S_{ss}^{\Delta} = A_{ss}^{\Delta}. \tag{107}$$

The stationary system is represented by eight equations:

Production function:
$$y_t = \left(\frac{1}{\Delta a_t}\right) L_t^{\gamma} \left(\frac{k_{t-1}}{\Delta k_t}\right)^{1-\gamma}. \tag{108}$$

Capital accumulation equation:
$$k_t = (1 - \delta)\frac{k_{t-1}}{\Delta k_t} + i_t, \tag{109}$$

Market clearing condition:
$$y_t = c_t + i_t + s_t, \tag{110}$$

Euler equation:
$$\frac{E[c_{t+1}\Delta c_{t+1}]}{c_t} = \beta(1 + r), \tag{111}$$

Definition of the real rate:
$$(1 - \gamma)\frac{E[y_{t+1}\Delta y_{t+1}]}{k_t} = r + \delta. \tag{112}$$

Optimality condition with respect to R&D capital:

$$1 + r_t = \frac{E[p_{t+1}^A]}{p_t^A}(1 - \delta^{RD}) + \frac{1}{p_t^A}\gamma E[y_{t+1}\Delta y_{t+1}] \tag{113}$$

Optimality condition for the capital producer:

$$\frac{p_t^A}{\Delta a_t} \upsilon\left(s_t\right)' e^{u_t} = 1 - s_t^{RD}. \tag{114}$$

Finally, the R&D capital accumulation equation:

$$\Delta a_t \equiv \frac{A_t}{A_{t-1}} = \left[1 - \delta^d + \upsilon\left(s_t\right) e^{u_t}\right]. \tag{115}$$

We compute the linear approximation to the solution of this system and the responses to an impulse in the government subsidy s_t^{RD}. We repeat the exercise using the mechanical approach. The file with the automatically stationarized model is in Appendix J. Figure 4 shows that the two solutions are identical.

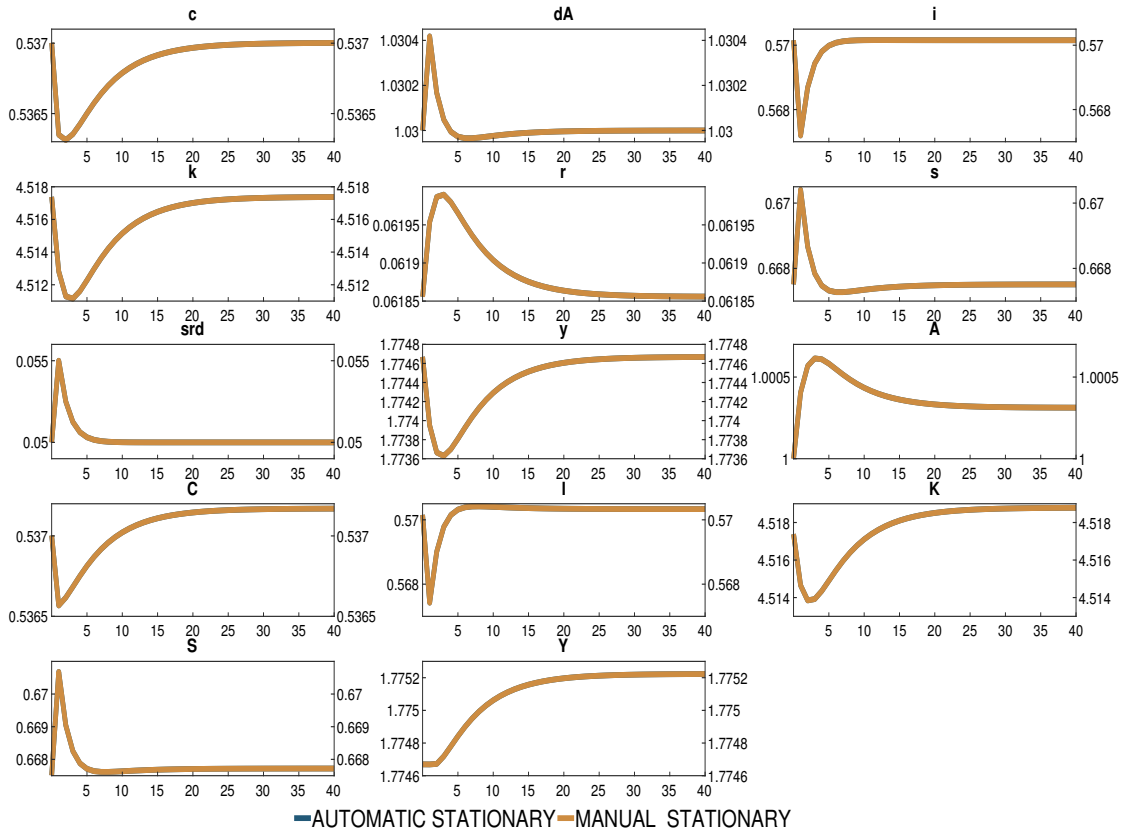

Figure 4: Responses to a subsidy shock

6   Comparison with other packages

Although other toolboxes have the capabilities to deal with non-stationary models, they are more restrictive in what the user is allowed to do and require crucial inputs in the stationarization process.

DYNARE has a symbolic facility designed to transform the first order conditions of a non-stationary model. However, to implement the transformation the user needs to provide both the growth factors and the endogenous variables that are trending. Furthermore, at least in its current format, DYNARE only accepts exogenous unit root process and can not deal e.g. with deterministic trends or endogenous growth. In Appendix K we provide a DYNARE code to solve the RBC example of Section 5.1 and the responses which as generated by an impulse in the labour augmenting disturbances.

IRIS, on the other hand, uses a numerical approach to transform the first-order conditions of the problem into a stationary format. Relative to IRIS, our algorithm has a number of advantages. First with IRIS the user needs to provide the growth path around which the numerical approximation is taken; this is automatically found with our approach. Second, we use a symbolic approach, which is free from numerical approximation error; third, our setup gives the user the possibility to inspect the G^i functions and understand how the model has been made stationary; finally the stationary model our approach produces can be used in other packages.

7   Conclusion

As Lafourcade and de Wind (2012) have noticed "... setting up, solving and estimating a DSGE that includes multiple theoretically-founded trends is a non-trivial exercise". The algorithm we provide makes this process less painful and less subject to algebraic mistakes. The approach is simple and straightforward; it allows a researcher to compare the consequences of different trend assumptions and to select the one which is more likely to characterize the available data. All of this, without tedious algebra and the risk of having to redo the computations several times. The algorithm we propose uses symbolic language and prepackaged MATLAB routines to generate the stationary system. Once this is obtained the model can be solved and standard dynamic analysis performed.

The codes used in the paper belong to the NB toolbox developed by Kenneth S. Paulsen. The toolbox is freely available, and downloadable at `https://github.com/Coksp1/NBTOOLBOX/`. The same location contains the files needed to replicate the examples of Sections 5.1, 5.2, 5.3 (`https://github.com/Coksp1 /NBTOOLBOX/tree/main/Examples/Econometrics/DSGE/Non_stationary_model`).

A Description of how the algorithm is implemented

The algorithm utilizes different classes existing in the NB toolbox:

1. The model file is parsed, and written into a MATLAB function handle.

2. The process of finding the restrictions imposed on the balanced growth path is performed utilizing the `nb_bgrowth` class. First, endogenous and exogenous variables, unit root process and parameters are transformed to a set of `nb_bgrowth` objects which are passed to the MATLAB function handle representing the equations of the model. The result is the set of restrictions holding along the balanced growth path.

3. The initial solution for the balanced growth path is obtained by transforming the equations found in step 2 to a linear system. From this solution it is possible to identify the R non-stationary variables.

4. The identification of the R the G^i functions is done with the function `nb_findBasis`. To get the symbolic representation of the G^i's, we first construct a function handle representing these equations, and then utilize the `nb_term` class and subclasses to transform it into symbolic equations.

5. The stationary representation of the model is constructed using `nb_stTerm`. This requires transforming the endogenous and exogenous variables and unit root variables to class `nb_stTerm` objects using the solution for the balanced growth. The parameters are transformed to `nb_stParam` objects. Then these objects are passed to the MATLAB function handle representing the non-stationary equations. The result is the stationary representation written in the model file syntax.

6. With the stationary representation, the model can be solved in a standard way. The examples presented in the paper utilizes the `myAD` [2], or `nb_mySD` classes. Again, endogenous and exogenous variables, unit root process and parameters are transformed to a set of objects which are passed to the MATLAB function handle representing the stationary equations of the model. The result is a set of matrices representing the linearized system, which is solved by Klein (2000) algorithm.

Step 1 uses the `nb_dsge` class constructor; steps 2-4 the `nb_dsge.solveBalancedGrowthPath` method[3], while step 5 employs the `nb_dsge.stationarize` method. The final step is performed by the `nb_dsge.solve` method. The following command allow one to perform model-based analysis once the solution is found:

IRFs Produces impulse response functions using the method `nb_dsge.irf`.

Theoretical moments Produce the theoretical moments of the model using the method nb_dsge.theoreticalMome

---

[2]Original code is written by SeHyoun Ahn, and can be found here https://github.com/sehyoun/MATLABAutoDiff

[3]A method is a function that is related to a class. For example the nb_dsge.solveBalancedGrowthPath method is a function that act on an object of class nb_dsge.

Filter If `nb_dsge` is assigned to data, using the `nb_dsge.set` method, you can run the Kalman filter using the `nb_dsge.filter` method. See also the `nb_dsge.getFiltered` method.

Forecast If the model is filtered, forecast can be produced using the `nb_dsge.forecast` method. See also `nb_dsge.getForecast` and `nb_dsge.plotForecast` methods.

B   The details of the RBC model

The production function is

$$Y_t = (A_t L_t)^\gamma K_{t-1}^{1-\gamma}, \tag{116}$$

where Y_t is output, $L_t = 1$ is labor, K_t is capital, A_t is the labor augmenting productivity, and γ is the labor share. Let I_t be investment and δ is the depreciation rate. Capital accumulates according to

$$K_t = (1 - \delta)K_{t-1} + I_t, \tag{117}$$

A representative household maximizes the discounted utility

$$E\left[\sum_{s=0}^{\infty} \beta^s U(C_{t+s})\right], \tag{118}$$

where β is the discount factor, subject to (116), (117) and the constraint

$$B_t + Y_t = C_t + I_t(1 + r_{t-1})B_{t-1} + T_t, \tag{119}$$

where B_t are one period bond issued by the government. The government collects lump sum taxes, T_t, from the households.

The optimality condition is

$$\frac{E[C_{t+1}]}{C_t} = \beta(1 + r_t), \tag{120}$$

where r_t, the real interest rate, is given by

$$r_t = (1 - \gamma)\frac{E[Y_{t+1}]}{K_t} - \delta. \tag{121}$$

Markets must also clear

$$Y_t = C_t + I_t. \tag{122}$$

(120)-(121) together with (116), (117) , (122), determine the equilibrium.

C   The details of the New Keynesian model

Final good sector

The final goods sector combines intermediate goods, $Q_t(n)$ into a final good A_t sold at a price P_t. The production function is:

$$Q_t = \left[\int_0^1 Q_t(n)^{1-\frac{1}{\theta_t^H}} \, dn \right]^{\frac{\theta_t^H}{\theta_t^H - 1}}. \tag{123}$$

where θ_t^H is the elasticity of substitution between different intermediate goods, and it assumed to follow an AR process. The optimal combination of $Q_t(n)$ is found by cost minimization

$$\min_{\{Q_t(n)\}} \int_0^1 P_t^Q(n) Q_t(n) dn,$$

subject to (123). The resulting optimality condition is:

$$Q_t(n) = \left(\frac{P_t^Q(n)}{P_t^Q} \right)^{-\theta_t^H} Q_t, \tag{124}$$

where

$$P_t^Q = \left[\int_0^1 P_t^Q(n)^{1-\theta_t^H} dn \right]^{\frac{1}{1-\theta_t^H}}. \tag{125}$$

Final good firms maximize the profit function

$$PA_t - P_t^Q Q_t, \tag{126}$$

subject to

$$A_t = Q_t. \tag{127}$$

The optimality condition is

$$P_t = P_t^Q. \tag{128}$$

Intermediate goods sector

Intermediate goods firms use effective capital and labor to produce a good which is sold under monopolistic competition to the final goods sector. The intermediate firm n has the production function

$$Q_t(n) = (Z_t z_t^L L_t(n))^{1-\alpha} \overline{K}_t(n)^\alpha, \tag{129}$$

where $\alpha \in [0,1]$ is the capital share, $L_t(n)$ and $\overline{K}_t(n)$ denote hours and effective capital of firm n in period t. There are two shocks to productivity: Z_t, a permanent labor-augmenting technology process, growing at the gross rate π_t^z, and z_t^L, a temporary shock to productivity (or labor utilization). Total labor input to firm n aggregate labor inputs from all households j:

$$L_t(n) = \left[\int_0^1 L_t(n,j)^{1-\frac{1}{\psi_t}} dj \right]^{\frac{\psi_t}{\psi_t-1}}, \tag{130}$$

33

where ψ_t is the elasticity of substitution between differentiated labor. Let W_t be the wage rate and R_t^K the rental rate. Minimizing total factor outlays:

$$W_t L_t(n) + R_t^K \overline{K}_t(n),$$

subject to 129 leads to the following first order conditions

$$L_t = (1 - \alpha) \frac{MC_t}{W_t} Q_t(n), \tag{131}$$

$$\overline{K}_t = \alpha \frac{MC_t}{R_t^K} Q_t(n), \tag{132}$$

where MC_t is marginal cost. In symmetric equilibrium all n firms make the same decision, so $L_t = L_t(n)$, $\overline{K}_t = \overline{K}_t(n)$ and $Q_t = Q_t(n)$. Firm n will minimize labor costs subject to the optimal level of labor input:

$$\min_{l_{I,t}(n,j)} \int_0^1 L_t(n,j) W_t(j) dj, \tag{133}$$

subject to

$$\left[\int_0^1 L_t(n,j)^{1 - \frac{1}{\psi_t}} dj \right]^{\frac{\psi_t}{\psi_t - 1}} = L_t(n). \tag{134}$$

Thus the conditional labor demand functions facing household j is

$$L_t(j) = \left(\frac{W_t(j)}{W_t} \right)^{-\psi_t} L_t. \tag{135}$$

Firms in the intermediate sector sell their goods monopolistically. Each firm n charges the $P_t^Q(n)$. Profits paid out as dividends to households) are:

$$\Pi_t(n) = P_t^Q(n) Q_t(n) - W_t L_t(n) - R_t^K(n) \overline{K}_t(n). \tag{136}$$

The costs of adjusting prices are

$$\gamma_{PQ,t}(n) \equiv \frac{\phi^{PQ}}{2} \left[\frac{P_t^Q(n)/P_{t-1}^Q(n)}{P_{t-1}^Q/P_{t-2}^Q} - 1 \right]^2, \tag{137}$$

where $P_t^Q = \left[\int_0^1 P_t^Q(n)^{1-\theta_t^H} dn \right]^{\frac{1}{1-\theta_t^H}}$. The costs of changing prices is governed by the parameter ϕ^{PQ}. These costs are assumed to be intangible. The intermediate firm n faces the demand function: $Q_t(n) = \left(\frac{P_t^Q(n)}{P_t^Q} \right)^{-\theta_t^H} Q_t$ Optimal price setting for firm n requires maximizing [4]:

---

[4]To make the expression easier to work with, the costs of adjusting prices are linear in $P_t^Q Q_t$ and not $P_t^Q(n)Q_t(n)$

$$\Pi_s = \sum_{t=s}^{\infty} \Delta_{s,t} \left\{ \begin{array}{c} P_t^Q(n) \left(\frac{P_t^Q(n)}{P_t^Q} \right)^{-\theta_t^H} Q_t - MC_t \left[\left(\frac{P_t^Q(n)}{P_t^Q} \right)^{-\theta_t^H} Q_t \right] \\ -\gamma_{PQ,t}(n) P_t^Q Q_t \end{array} \right\}.$$

In symmetric equilibrium, all firms will behave the same, and thus:

$$Q_t - \theta_t^H Q_t + MC_t \theta_t^H \frac{Q_t}{P_t^Q} - \phi^{PQ} \left[\frac{P_t^Q/P_{t-1}^Q}{P_{t-1}^Q/P_{t-2}^Q} - 1 \right] \frac{P_t^Q/P_{t-1}^Q}{P_{t-1}^Q/P_{t-2}^Q} Q_t$$

$$+ E_t \left\{ \Delta \phi^{PQ} \left[\frac{P_{t+1}^Q/P_t^Q}{P_t^Q/P_{t-1}^Q} - 1 \right] \frac{(P_{t+1}^Q/P_t^Q)^2}{P_t^Q/P_{t-1}^Q} Q_{t+1} \right\} = 0. \tag{138}$$

Investment producer

Perfectly competitive firms purchase Y_t^I units from the final good producers, and produce investment goods I_t according to the production function

$$I_t = \Upsilon_t Y_t^I. \tag{139}$$

Υ_t represents investment-specific technological (IST) progress, which is specified later, and I_t is the investment good sold to capital producers. The objective of investment producers is to maximize the profit function

$$P_t^I I_t - P_t Y_t^I, \tag{140}$$

subject to (139). The optimal condition is:

$$\Upsilon_t P_t^I = P_t. \tag{141}$$

Capital producer

Capital goods, K_t^{new}, are produced by a sector which purchases investment goods I_t and transform them into capital, sold to households at price P_t^K. The production function is:

$$K_t^{new} = z_{I,t} \left(1 - S \left(\frac{I_t}{I_{t-1}} \right) \right) I_t. \tag{142}$$

S captures the presence of adjustment costs in investment. $z_{I,t}$ is the marginal efficiency of investment shock process. The objective of capital producers is to maximize the expected discounted future profits:

$$E_s \sum_{t=s}^{\infty} \Delta_{s,t} \left[P_t^K K_t^{new} - P_t^I I_t \right], \tag{143}$$

35

subject to (139). Optimality implies:

$$E\left[\Delta P_{t+1}^K z_{I,t+1} S_2'\left(\frac{I_{t+1}}{I_t}\right) I_{t+1}\right] + P_t^K z_{I,t}\left[1 - S\left(\frac{I_t}{I_{t-1}}\right) - S_1'\left(\frac{I_t}{I_{t-1}}\right) I_t\right] - P_t^I = 0, \qquad (144)$$

where we assume that

$$S\left(\frac{I_t}{I_{t-1}}\right) = \frac{\phi_{I1}}{2}\left[\frac{I_t}{I_{t-1}} - \left(\pi_{ss}^{\Upsilon}\right)^{\frac{1}{1-\alpha}} \pi_{ss}^z\right]^2, \qquad (145)$$

Thus

$$S_1'\left(\frac{I_t}{I_{t-1}}\right) = \phi_{I1}\left[\frac{I_t}{I_{t-1}} - \left(\pi_{ss}^{\Upsilon}\right)^{\frac{1}{1-\alpha}} \pi_{ss}^z\right]\frac{1}{I_{t-1}}, \qquad (146)$$

$$S_2'\left(\frac{I_t}{I_{t-1}}\right) = -\phi_{I1}\left[\frac{I_t}{I_{t-1}} - \left(\pi_{ss}^{\Upsilon}\right)^{\frac{1}{1-\alpha}} \pi_{ss}^z\right]\frac{I_t}{I_{t-1}^2}, \qquad (147)$$

Households

Each household supplies a differentiated labor input to intermediate firms and set wages under the assumption of monopolistic competition. Households obtain utility from consumption and leisure. Preferences are additively separable. Lifetime expected utility of household j at time s is

$$U_s(j) = E_s \sum_{t=s}^{\infty} \beta^{t-s} \rho_t \left[u\left(C_t(j)\right) - v(L_t(j))\right], \qquad (148)$$

where β is the discount factor, ρ_t is a discount factor shock, C_t denotes consumption, and L_t labor. The in-period utility function is

$$u\left(C_t(j)\right) = z_t^u\left(1 - \frac{b^c}{(\pi_{ss}^{\Upsilon})^{\frac{\alpha}{1-\alpha}} \pi_{ss}^z}\right)\ln\left[\frac{C_t(j) - b^c C_{t-1}}{\left(1 - \frac{b^c}{(\pi_{ss}^{\Upsilon})^{\frac{\alpha}{1-\alpha}} \pi_{ss}^z}\right)}\right], \qquad (149)$$

$$\nu\left(L_t(j)\right) = \frac{1 - b^l}{1+\zeta}\left[\frac{L_t(j) - b^l L_{t-1}}{1 - b^l}\right]^{1+\zeta}, \qquad (150)$$

b^c governs habit persistence, π_{ss}^z denotes the steady-state labor augmenting technology growth rate and π_{ss}^{Υ} the steady-state investment-specific technology growth rate. The degree of disutility of supplying labor is captured by $\zeta > 0$, the inverse Frisch elasticity. As (149) indicates, we assume a log in-period utility function for consumption. This insure the existence of a balanced growth path. The household's budget constraint is

$$P_t C_t(j) + P_t^K K_t^{new}(j) + P_t B_t(j) + P_t \gamma(U_t) K_{t-1}$$
$$+ W_t(j) L_t(j) \gamma_t(j) + T_t(j)$$
$$\leq R_{t-1} P_{t-1} B_{t-1}(j) + W_t(j) L_t(j) + R_t^K U_t K_{t-1} \tag{151}$$
$$+ Q_t(j) + \Pi_t(j) + DIV_t(j),$$

where P_t is the price level of final goods, R_t is the gross interest rate, $B_t(j)$ is real household's borrowing, $W_t(j)$ is the nominal wage rate set by household j, $\gamma_t(j)$ is intangible wage adjustment costs (defined in (156)), $L_t(j)$ is the total hours worked, and $DIV_t(j)$, $\Pi_t(j)$ and $T_t(j)$ are is the net cash flow from household's j portfolio of state contingent securities, profits (in nominal terms) paid out and taxes paid, respectively. Households rent out utilized capital $U_t K_{t-1}$ at the rate R_t^K, where U_t is the utilization rate and K_{t-1} the capital stock at the end of last period. We assume intangibility of the utilization cost. $K_t^{new}(j)$ is new capital bought from the capital producers at price P_t^K and $\gamma(U_t) K_{t-1}$ is a cost specified and:

$$\gamma(U_t) = \frac{R_{ss}^K}{P_{ss} \phi_u} \left[e^{\phi_u(U_t-1)} - 1 \right], \tag{152}$$

where ϕ_u governs the cost of adjusting utilization. Time t utilized capital iis

$$\overline{K}_t = U_t K_{t-1}. \tag{153}$$

The physical capital accumulation equation is

$$K_t = (1 - \delta) K_{t-1} + K_t^{new}. \tag{154}$$

Household j faces the following labor demand curve:

$$L_t(j) = \left(\frac{W_t(j)}{W_t} \right)^{-\psi_t} L_t, \tag{155}$$

where W_t is the wage rate. We further assume that there is sluggish wage adjustment due to resource costs measured in terms of the total wage bill. We deviate from JPT, and assume that wage adjustments costs are

$$\gamma_t(j) \equiv \frac{\phi^W}{2} \left[\frac{W_t(j)/W_{t-1}(j)}{W_{t-1}/W_{t-2}} - 1 \right]^2. \tag{156}$$

Thus, costs are related to changes in wage inflation relative to the past observed rate for households. $\phi^W > 0$ determines how costly it is to change the wage inflation rate. Maximizing (148) subject to the budget constraint leads to the following optimal conditions in symmetric equilibrium

$$E_t \left[\beta \frac{\rho_{t+1} u'(C_{t+1})}{\rho_t u'(C_t)} \frac{P_t}{P_{t+1}} \right] R_t = 1 \tag{157}$$

$$\frac{v'(L_t)}{u'(C_t)} \psi_t \frac{P_t}{W_t} = \left[(\psi_t - 1)(1 - \gamma_t) + \phi^W \left(\frac{W_t/W_{t-1}}{W_{t-1}/W_{t-2}} - 1 \right) \frac{W_t/W_{t-1}}{W_{t-1}/W_{t-2}} \right]$$
$$- E_t \left[\beta \frac{\rho_{t+1} u'(C_{t+1})}{\rho_t u'(C_t)} \frac{P_t}{P_{t+1}} \frac{L_{t+1}}{L_t} \phi^W \left(\frac{W_{t+1}/W_t}{W_t/W_{t-1}} - 1 \right) \frac{(W_{t+1}/W_t)^2}{W_t/W_{t-1}} \right], \tag{158}$$

$$\rho_t u'(C_t) \frac{P_t^K}{P_t} = E_t \left[\beta \rho_{t+1} u'(C_{t+1}) \left(\frac{P_{t+1}^K}{P_{t+1}} (1 - \delta) + \frac{R_{K,t+1}}{P_{t+1}} U_{t+1} - \gamma(U_{t+1}) \right) \right], \tag{159}$$

$$\frac{R_{K,t}}{P_t} = \gamma'(U_t) \frac{R_{K,ss}}{P_{ss}} e^{\phi_u(U_t - 1)}. \tag{160}$$

Final good market clearing and definitions

$$\widetilde{A}_t = \widetilde{C}_t + \widetilde{Y}_t^I. \tag{161}$$

Inflation

$$\pi_t \equiv \frac{P_t}{P_{t-1}}. \tag{162}$$

Intermediate goods inflation

$$\pi_t^Q = \frac{P_t^Q}{P_{t-1}^Q}. \tag{163}$$

Investment price inflation

$$\pi_t^I = \frac{P_t^I}{P_{t-1}^I}. \tag{164}$$

Capital price inflation

$$\pi_t^K = \frac{P_t^K}{P_{t-1}^K}. \tag{165}$$

Wage inflation

$$\pi_t^W = \frac{W_t}{W_{t-1}}. \tag{166}$$

Output

$$Y_{NAT,t} = A_t. \tag{167}$$

Output growth

$$\Delta Y_{NAT,t} = \frac{A_t}{A_{t-1}}. \tag{168}$$

The Monetary policy rule is

$$R_t = (R_{t-1})^{\omega_R} \left(R_{ss} \left(\frac{\pi_t}{\pi_{ss}} \right)^{\omega_P} \left(\frac{\widetilde{Y}_{NAT,t}}{\widetilde{Y}_{NAT,ss}} \right)^{\omega_Y} \left(\triangle \widetilde{Y}_{NAT,t} \right)^{\omega_{\triangle Y}} \right)^{1-\omega_R} e^{z_{R,t}}, \tag{169}$$

where ω_R ω_P, ω_Y and $\omega_{\triangle Y}$ are the weights on past nominal rate, inflation, output gap and output growth; and $z_{R,t}$ is a monetary policy shock.

The shock processes

Labor augmenting technology shock:

$$\log \left(\frac{Z_t}{Z_{t-1}} \right) = \log(\pi_t^z) = (1 - \lambda_{\pi^z}) \log(\pi_{ss}^z) + \lambda_{\pi^z} \log(\pi_{t-1}^z) + \epsilon_{\pi^z,t} \sigma_{\pi^z}. \tag{170}$$

Investment-specific technological shock:

$$\log \left(\frac{\Upsilon_t}{\Upsilon_{t-1}} \right) = \log(\pi_t^{\Upsilon}) = (1 - \lambda_{\pi^{\Upsilon}}) \log(\pi_{ss}^{\Upsilon}) + \lambda_{\pi^{\Upsilon}} \log(\pi_{t-1}^{\Upsilon}) + \epsilon_{\pi^{\Upsilon},t} \sigma_{\pi^{\Upsilon}}. \tag{171}$$

Intermediate good sector productivity shock:

$$\log(z_t^L) = (1 - \lambda_{z^L}) \log(z_{ss}^L) + \lambda_{z^L} \log(z_{t-1}^L) + \epsilon_{z^L,t} \sigma_{z^L}. \tag{172}$$

Labor market competition shock:

$$\log(\psi_t) = (1 - \lambda_{\psi}) \log(\psi_{ss}) + \lambda_{\psi} \log(\psi_{t-1}) + \epsilon_{\psi,t} \sigma_{\psi}. \tag{173}$$

Intermediate good market competition shock:

$$\log(\theta_t^H) = (1 - \lambda_{\theta^H}) \log(\theta_{ss}^H) + \lambda_{\theta^H} \log(\theta_{t-1}^H) + \epsilon_{\theta^H,t} \sigma_{\theta^H}. \tag{174}$$

Marginal efficiency of investment shock:

$$\log(z_{I,t}) = (1 - \lambda_I) \log(z_{I,ss}) + \lambda_I \log(z_{I,t-1}) + \epsilon_{I,t} \sigma_I. \tag{175}$$

Monetary policy shock:

$$\log(z_{R,t}) = (1 - \lambda_R) \log(z_{R,ss}) + \lambda_R \log(z_{R,t-1}) + \epsilon_{R,t} \sigma_R. \tag{176}$$

Consumption preference shock:

$$\log(z_t^u) = (1 - \lambda_{z^u}) \log(z_{ss}^u) + \lambda_{z^u} \log(z_{t-1}^u) + \epsilon_{z^u,t} \sigma_{z^u}. \tag{177}$$

Discount factor shock:

$$\log(\rho_t) = (1 - \lambda_{\rho}) \log(\rho_{ss}) + \lambda_{\rho} \log(\rho_{t-1}) + \epsilon_{\rho,t} \sigma_{\rho}. \tag{178}$$

where λ_j regulates persistence and σ_j the standard deviation, $j = 1 \ldots, 9$

H   Generating results from the JPT model

In the main paper we have calculated the steady state, balanced growth path and moments. In this section we present the code on how you can calculate these tables using NB toolbox.

```
